A deep dive on ERC-20 contract vulnerabilities

No Author Given

No Institute Given

Abstract. ERC-20 is the most prominent Ethereum standard for transferable tokens. Tokens implementing the ERC-20 interface can interoperate with a large number of already deployed internet-based services and Ethereum-based smart contracts. In recent years, security vulnerabilities in ERC-20 implementations have been uncovered. We (i) systemize these across 7 auditing tools into a set of 82 distinct vulnerabilities and best practices, and (ii) use our experience to provide a new secure implementation of the ERC-20 interface, TokenHook, that is freely available and open source.[1]. We also (iii) analyze the top ten ERC-20 tokens by market capitalization for comparison.

1 Introduction

The Ethereum blockchain project was launched in 2014 by announcing Ether (ETH) as its protocol-level cryptocurrency [16,70]. Ethereum allows users to build and deploy decentralized applications (DApps), or smart contracts, that can accept and use ETH. Many DApps also issue their own custom tokens with a variety of intents, including tokens as: financial products, in-house currencies, voting rights for DApp governance, valuable assets, crypto-collectibles, *etc.* To encourage interoperability with other DApps and web apps (exchanges, wallets, *etc.*), the Ethereum community accepted a popular token standard (for non-fungible tokens) called ERC-20 [24]. While numerous ERC-20 extensions or replacements have been proposed, ERC-20 remains prominent. Of the 2.5M[49] smart contracts on the Ethereum network, 260K are tokens [62]. 98% of these tokens are ERC-20 [21], demonstrating their widespread acceptance by the industry and Ethereum community.

The development of smart contracts has been proven to be error-prone, and as a result, smart contracts are often riddled with security vulnerabilities. An early study in 2016 found that 45% of smart contracts at that time had vulnerabilities[36]. ERC-20 token are subset of smart contracts and security is particularly important given that many tokens have considerable market capitalization (*e.g.,* USDT, LINK, CRO, LEO, DAI, *etc.*). As tokens can be held by commercial firms, in addition to individuals, and firms need audited financial statements in certain circumstances, the correctness of the contract issuing the tokens is now in the purview of professional auditors. One tool we examine, EY Smart Contract and Token Review[23], is from a 'big-four' auditing firm.

---

[1] Implementation on Etherscan with source code and deployed on Mainnet and Rinkeby: `https://bit.ly/35FMbAf`, `https://bit.ly/33wDENx`

Contributions. Similar to any new technology, Ethereum has undergone numerous security attacks that have collectively caused more than US$100M in financial losses[26,44,42,53,45,3]. Although research has been done on smart contract vulnerabilities in the past[30], our focus is on ERC-20 tokens only. Some vulnerabilities (such as multiple withdrawals) will be more serious in token contracts. This motivates us to (i) comprehensively study all known vulnerabilities in ERC-20 token contracts, systematizing them into a set of 82 distinct vulnerabilities and best practices, and review the completeness and precision of auditing tools in detecting these vulnerabilities to establish the reliability of an audit based on these tools. We (ii) use this research to provide a new secure implementation of the ERC-20 interface, TokenHook, that is freely available and open source. Compared to other implementations from OpenZeppelin[40] and ConsenSys[7], it is more secure and fully compatible with ERC-20 specifications (see section3). Finally, (iii) we examine the practicality of our work in the context of the top ten ERC-20 tokens by market capitalization.

2   TokenHook

ERC-20 vulnerabilities are a combination of generic DApp vulnerabilities, as well as specific attacks on the functions enforced by the ERC-20 interface. In section 5.1, we examine general attack vectors[37,30,14,11,35] and cross-check their applicability to ERC-20 tokens. We then consider mitigation techniques in the implementation of TokenHook and apply best practices to improve performance.

Among the layers of the Ethereum blockchain, our focus is on the *Contract layer* in which DApps are executed. The presence of security vulnerability in supplementary layers affect the entire Ethereum blockchain, not necessarily ERC-20 tokens. Therefore, vulnerabilities in other layers are assumed to be out of the scope (*e.g., Indistinguishable chains* at the data layer, the *51% attack* at the consensus layer, *Unlimited nodes creation* at network layer, and *Web3.js Arbitrary File Write* at application layer). Moreover, we exclude vulnerabilities identified in now outdated compiler versions, for example:

- *Constructor name ambiguity* in versions before 0.4.22.
- *Uninitialized storage pointer* in versions before 0.5.0.
- *Function default visibility* in versions before 0.5.0
- *Typographical error* in versions before 0.5.8.
- *Deprecated solidity functions* in versions before 0.4.25.
- *Assert Violation* in versions before 0.4.10.
- *Under-priced DoS attack* before EIP-150 & EIP-1884.

TokenHook, our ERC20-compliant token implementation written in Solidity. The source code is available on Etherscan, where it has been tested with MetaMask and deployed on Mainnet[2]. TokenHook can be customized by developers, who can refer to each mitigation technique separately and address a specific attack. Required comments in NatSpec format[17] have been also added to clarify usage of each part. Standard functionalities of the token (*i.e.,* approve(),

---

[2] Etherscan: `https://bit.ly/35FMbAf`

`transfer()`, *etc.*) have been unit tested. A demonstration of token interactions and event triggering can also be seen on Etherscan[3]. Top features of TokenHook can be highlighted as follows:

1. Using `SafeMath` library in arithmetic operations to catch over/under flows.
2. Implementing `noReentrancy` modifier to enforce Mutex in addition to CEI to mitigate re-entrancy attack.
3. Checking the returned value of `call.value()` and revert failed fund transfers in `sell()` and `withdraw()` functions.
4. Explicitly define visibility of each function per specification of ERC-20. Interactive functions (*e.g.,* `Approve()`, `Transfer()`, *etc.*) are publicly accessible.
5. Adding a new state variable to the `transferFrom()` function to track transferred tokens and mitigate the *multiple withdrawal attack*.
6. Defining `withdraw()` function which allows the owner to transfer ETH out of the token contract (*Frozen Ether* mitigation). If necessary, developers can require multiple signatures to withdraw ETH.
7. Using `onlyOwner` modifier to enforce authentication on `withdraw()` function before sending out any funds (*Unprotected Ether Withdrawal* mitigation). If necessary, this modifier can be extended to require multiple approvals.
8. Using `Library` keyword to declare `SafeMath` library as an embedded library. Its code will be added to the ERC-20 contract's code and EVM uses `JUMP` opcode instead of `DELEGATECALL` (*State variable manipulation* mitigation).
9. Implementing all functions to make it fully compatible with the standard.
10. Defining six extra events: `Buy`, `Sell`, `Received`, `Withdrawal`, `Change` and `Pause`. These can be used to watch for token inconsistent behavior (*e.g.,* via TokenScope tool[5]) and react accordingly.

The authors of the ERC-20 standard reference two sample implementations from OpenZeppelin[40] and ConsenSys[7]. ConsenSys implementation is deprecated (according to their GitHub page). We therefore consider only OpenZeppelin implementation for comparison. TokenHook has the following advantages:

- Unlike OpenZeppelin which introduces two new functions to mitigate *multiple withdrawal attack* (*i.e.,* `increaseAllowance()` and `decreaseAllowance()`), TokenHook secures standard ERC-20 function (*i.e.,* `transferFrom()`). DApps can interact with standard `approve()` and `transferFrom()` methods without adapting their code to new functions. TokenHook is therefore fully compliant with the ERC-20 specification and can interact with already developed and legacy DApps.
- TokenHook mitigate *Frozen Ether* issue by introducing `withdraw()` function while sent ETH to OpenZeppelin contract are unrecoverable.
- *Fail-Safe Mode* is a built-in feature of TokenHook while OpenZeppelin requires incorporation of `Pausable.sol` contract.
- OpenZeppelin requires other optimizations such as *Locking the pragma*, Emitting *Change* event (*cf.* TokenScope[5]) when updating state variables (*e.g.,* _decimals = decimals_ in `_setupDecimals()`), *Initializing totalSupply in constructor*, using `External` visibility instead of Public to increase readability

---

[3] Etherscan: `https://bit.ly/33xHfL2`, `https://bit.ly/35TimMW`

(*i.e.,* no internal call) and consume less gas, Avoiding similar variable names (*e.g.,* _name = name_ in `constructor()`), Using mixedCase format when declaring variable and functions (*e.g.,* _symbol, _decimals), *etc.*

- Using reusable codes has made the OpenZeppelin code complex and challenging for security tools. Developers need to manually check the code for vulnerabilities instead of using vulnerability assessment tools. Additionally, most of the security tools are not able to import libraries/interfaces from external files (*e.g.,* SafeMath.sol, IERC20.sol). TokenHook has flat layout and all codes are in one file. It is easier for developers to understand and modify it. It can be also directly uploaded to audit tools without any modification.
- Having different ERC-20 implementation minimizes the possibility of bugs that existed in the past. Between 17 March 2017 and 13 July 2017, OpenZeppelin implemented the wrong interface in their framework that affected 130 tokens[9]. Diversity in ERC-20 implementation can reduce the impact of such errors.

In addition to the standard ERC-20 methods, we also implement complementary features such as `sell()` and `buy()` for exchanging tokens and ETH. `sell()` allows token holders to exchange tokens for ETH and `buy()` accepts ETH by adjusting buyer's token balance. This can be considered as a financial incentive in which it is possible to buy and sell tokens at a fixed price by the token contract. Otherwise, buyers will have to wait for the token to be listed on crypto-exchanges (if it ever happens) or look for a buyer themselves. In addition, it reduces the cost of token exchange by eliminating crypto-exchange's fees.

3 Audit Tools

We used a variety of code audit tools on TokenHook to validate the code and also to illuminate the completeness and error-rate of such tools on one specific use-case (similar work studies in less depth a variety of use-cases[2]):

1. EY Review Tool by Ernst & Young Global Limited[23].
2. SmartCheck by SmartDec[57].
3. Securify v2.0 by ChainSecurity[64].
4. ContractGuard by GuardStrike[27].
5. MythX by ConsenSys[6].
6. Slither Analyzer by Crytic[34].
7. Odin by Sooho[58].

We did not adapt older tools that support significantly lower versions of the Solidity compiler (*e.g.,* Oyente). A total of 82 audits have been conducted by these auditing tools. Audits include best practices and security vulnerabilities. The results are summarized in Tables1–3. To compile the list, we referenced the knowledge-base of each tool[63,57,6,27,34], understood each threat, manually mapped the audit to the corresponding SWC registry[56], and manually determined when different tools were testing for the same vulnerability or best practice (which was not always clear from the tools' own descriptions). Space will not permit us to discuss each one at the same level of detail as the ones we

Table 3. Continuation of Table2.

highlight in section5.1, however we will include a simple statement describing the issue and the mitigation.

Since each tool employs different methodology to analyze smart contracts (*e.g.,* comparing with violation patterns, applying a set of rules, using static analysis, *etc.*), there are false positives to manually check. The following are some examples of false positives (which we do not count in calculating our success rate):

- *MythX* detects *Re-entrancy attack* in the *noReentrancy* modifier. In Solidity, modifiers are not like functions. They are used to add features or apply some restriction on functions[55]. Using modifiers is a known technique to implement Mutex and mitigate the attack[65]. This is a false positive and note that other tools have not identified the attack in modifiers.
- *ContractGuard* flags *Re-entrancy attack* in `transfer()` function while both CEI and Mutex are implemented.
- *Slither* detects two *low level call* vulnerabilities[33]. This is due to use of `call.value()` that is recommend way of transferring ETH after *Istanbul* hard-fork (EIP-1884). Therefore, adapting analyzers to new standards can improve accuracy of the security checks.
- *SmartCheck* recommends not using `SafeMath` and check explicitly where overflows might be occurred. We consider this failed audit as false possible whereas utilizing `SafeMath` is a known technique to mitigate over/under flows. It also flags *using a private modifier* as a vulnerability by mentioning, "miners have access to all contracts' data and developers must account for the lack of privacy in Ethereum". However private visibility in Solidity concerns object oriented inheritance not confidentiality. For actual confidentiality, the best practice is to encrypt private data or store them off-chain. The tool also warns against `approve()` in ERC-20 due to *front-running attacks*. Despite EIP-1884, it still recommends using of `transfer()` method with stipend of 2300 gas. There are other false positives such as SWC-105 and SWC-112 that are passed by other tools.
- *Securify* detects the *Re-entrancy* attack due to unrestricted writes in the `noReentrancy` modifier[64]. Modifiers are the recommended approach and are not accessible by users. It also flags *Delegatecall to Untrusted Callee (SWC-112)* while there is no usage of `delegatecall()` in the code. It might be due to use of `SafeMath` library which is an embedded library. In Solidity, embedded libraries are called by JUMP commands instead of `delegatecall()`. Therefore, excluding embedded libraries from this check might improve accuracy of the tool. Similar to *SmartCheck*, it still recommends to use the `transfer()` method instead of `call.value()`.
- *EY token review* considers `decreaseAllowance` and `increaseAllowance` as standard ERC-20 functions and if not implemented, recognizes the code as vulnerable to a *front-running*. These two functions are not defined in the ERC-20 standard[24] and considered only by this tool as mandatory functions. There are other methods to prevent the attack while adhering ERC-20 specifications (see Rahimian *et al.* for a full paper on this attack and the ba-

sis of the mitigation in TokenHook [47]). The tool also falsely detects the *Overflow*, mitigated through `SafeMath`. Another identified issue is *Funds can be held only by user-controlled wallets*. The tool warns against any token transfer to Ethereum addresses that belong to smart contracts. However, interacting with ERC-20 token by other smart contracts was one of the main motivations of the standard. It also checks for maximum 50000 gas in `approve()` and 60000 in `transfer()` method. We could not find corresponding SWC registry or standard recommendation on these limitations and therefore consider them as informational.

- *Odin* raises *Outdated compiler version* issue due to locking solidity version to 0.5.11. We have used this version due to its compatibility with other auditing tools. Furthermore, other tools have not identified such an issue and we therefore consider it as informational.

After manually overriding the false positives, the average percentage of passed checks for TokenHook reaches to 99.5%. To pass the one missing check and reach a 100% success rate across all tools, we prepared the same code in Solidity version 0.8.0, however it cannot be audited anymore with most of the tools.

3.1 Comparing audits

We repeated the same auditing process on the top ten tokens based on their market cap[21]. The result of all these evaluation have been summarized in Table4 by considering false positives as failed audits. This provide the same evaluation conditions across all tokens. Since each tool uses different analysis methods, number of occurrences are considered for comparisons. For example, MythX detects two *re-entrancy* in TokenHook; therefore, two occurrences are counted instead of one. As it can be seen in Table 4, TokenHook has the least number of security flaws (occurrences) compared to other tokens. We stress that detected security issues for TokenHook are all false positives.

4 Conclusion

98% of tokens on Ethereum today implement ERC-20. While attention has been paid to the security of Ethereum DApps, threats to tokens can be specific to ERC-20 functionality. Further, there is no vulnerability reference site (*cf.* the SWC Registry) specifically for ERC-20 tokens. In this paper, we provide a detailed study of ERC-20 security, collecting and deduplicating 82 vulnerabilities and best practices, examining the ability of seven audit tools, and auditing 10 ERC-20 deployments. Most importantly, we provide a concrete implementation of ERC-20 called TokenHook. It is designed to be secure against known vulnerabilities. We test it at Solidity version 0.5.11 (due to the limitation of the audit tools) and also provide it at 0.8.0. TokenHook can be used as template to deploy new ERC-20 tokens, migrate current vulnerable deployments, and to benchmark the precision of Ethereum audit tools.

ERC-20 Token	Auditing Tool							Total issues
	EY Token Review	Smart Check	Securify	MythX (Mythril)	Contract Guard	Slither	Odin	
TokenHook	9	11	4	2	10	2	2	**40**

Table 4. Security flaws detected by seven auditing tools in TokenHook (the proposal) compared to top 10 ERC-20 tokens by market capitalization in May 2020. TokenHook has the lowest reported security issues (occurrences).

5 Appendices

5.1 A sample of high profile vulnerabilities

In this section, we sample some high profile vulnerabilities, typically ones that have been exploited in real world ERC-20 tokens. For each, we (i) briefly explain technical details, (ii) the ability to affect ERC-20 tokens, and (iii) discuss mitigation techniques.

5.1.1 Arithmetic Over/Under Flows. An *integer overflow* is a well known issue in many programming languages. For ERC-20, one notable exploit was in April 2018 that targeted the BEC Token[10] and resulted in some exchanges (*e.g.,* OKEx, Poloniex and HitBTC) suspending deposits and withdrawals of all tokens. Although BEC developers had considered most of the security measurements, only line 261 was vulnerable[25][44]. The attacker was able to pass a combination of input values to transfer large amount of tokens[46]. It was even larger than the initial supply of the token, allowing the attacker to take control of token financing and manipulate the price. In Ethereum, integer overflows do not throw an exception at runtime. This is by design and can be prevented by using the `SafeMath` library[41] wherein `a+b` will be replaced by `a.add(b)` and throws an exception in the case of arithmetic overflow.

5.1.2 Re-entrancy One of the most studied vulnerabilities is re-entrancy, which resulted in a US$50M attack on a DApp (called the DAO) in 2016 and triggered an Ethereum hard-fork to revert[26]. At first glance, re-entrancy might seem inapplicable to ERC-20 however any function that changes internal state, such as balances, need to be checked. Further, some ERC-20 extensions could also be problematic. One example is ORBT tokens[48] which support token exchange

with ETH without going through a crypto-exchange[54]: an attacker can call the exchange function to sell the token and get back equivalent in ETH. However, if the ETH is transferred in a vulnerable way before reaching the end of the function and updating the balances, control is transferred to the attacker receiving the funds and the same function could be invoked over and over again within the limits of a single transaction, draining excessive ETH from the token contract. This variant of the attack is known as *same-function re-entrancy*, but it has three other variants: *cross-function*, *delegated* and *create-based* [51]. Mutex[68] and CEI[13] techniques can be used to prevent it. In Mutex, a state variable is used to lock/unlock transferred ETH by the lock owner (*i.e.,* token contract). The lock variable fails subsequent calls until finishing the first call and changing requester balance. CEI updates the requester balance before transferring any fund. All interactions (*i.e.,* external calls) happen at the end of the function and prevents recursive calls. Although CEI does not require a state variable and consumes less Gas, developers must be careful enough to update balances before external calls. Implementation of Mutex is more efficient and blocks *cross-function* attacks at the beginning of the function regardless of internal update sequences. CEI can also be considered as a best practice and basic mitigation for the *same-function re-entrancy*.

5.1.3   Unchecked return values In Solidity, sending ETH to external addresses is supported by three options: `call.value()`, `transfer()`, or `send()`. The `transfer()` method reverts all changes if the external call fails, while the other two return a boolean value and manual check is required to revert transaction to the initial state[4]. Before the *Istanbul* hard-fork[1], `transfer()` was the preferred way of sending ETH. It mitigates reentry by ensuring ETH recipients would not have enough gas (*i.e.,* a 2300 limit) to do anything meaningful beyond logging the transfer when execution control was passed to them. EIP-1884[29] has increased the gas cost of some opcodes that causes issues with `transfer()`[4]. This has led to community advice to use `call.value()` and rely on one of the above re-entrancy mitigations (*i.e.,* Mutex or CEI)[38,50].

5.1.4   Public visibility In Solidity, visibility of functions are `Public` by default and they can be called by any external user/contract. In the Parity MultiSig Wallet hack[45], an attacker was able to call public functions and reset the ownership address of the contract, triggering a \$31M USD theft. It is recommended to explicitly specify visibility of functions instead of default `Public` visibility.

5.1.5   Multiple withdrawal This ERC-20-specific issue was originally raised in 2017[67,28]. It can be considered as a *transaction-ordering*[8] or *front-running*[15] attack. There are two ERC-20 functions (*i.e.,* `Approve()` and `transferFrom()`) that can be used to authorize a third party for transferring tokens on behalf

---

[4] After *Istanbul*, the `fallback()` function consumes more than 2300 Gas if called via `transfer()` or `send()` methods.

of someone else. Using these functions in an undesirable situation (*i.e.,* front-running or race-condition) can result in allowing a malicious authorized entity to transfer more tokens than the owner wanted. There are several suggestions to extend ERC-20 standard (*e.g.,* MonolithDAO[66] and its extension in OpenZeppelin[40]) by adding new functions (*i.e.,* `decreaseApproval()` and `increaseApproval()`), however, securing `transferFrom()` method is the effective one while adhering specifications of the ERC-20 standard[47].

5.1.6   Frozen Ether As ERC-20 tokens can receive and hold ETH, just like a user accounts, functions need to be defined to withdraw deposited ETH (including unexpected ETH). If these functions are not defined correctly, an ERC-20 token might hold ETH with no way of recovering it (*cf.* Parity Wallet[43]).

5.1.7   Unprotected Ether Withdrawal Improper access control may allow unauthorized persons to withdraw ETH from smart contracts (*cf.* Rubixi[52]). Therefore, withdrawals must be triggered by only authorized accounts and ideally multiple parties.

5.1.8   State variable manipulation The `DELEGATECALL` opcode in Ethereum enables a DApp to invoke external functions of other DApps and execute them in the context of calling contract (*i.e.,* the invoked function can modify the state variables of the caller). This makes it possible to deploy libraries once and reuse the code in different contracts. However, the ability to manipulate internal state variables by external functions has lead to incidents where the entire contract was hijacked (*cf.* the second hack of Parity MultiSig Wallet[3]). Preventive techniques is to use `Library` keyword in Solidity to force the code to be stateless, where data is passed as inputs to functions and passed back as outputs and no internal storage is permitted[19]. There are two types of Library: *Embedded* and *Linked*. Embedded libraries have only internal functions, in contrast to linked libraries that have public or external functions. Deployment of linked libraries generates a unique address on the blockchain while the code of embedded libraries will be added to the contract's code [31]. It is recommended to use Embedded libraries to mitigate this attack.

5.1.9   Balance manipulation ERC-20 tokens generally receive ETH via a *payable* function[18] (*i.e.,* `receive()`, `fallback()`, *etc.*), however, it is possible to send ETH without triggering payable functions, for example via `selfdestruct()` that is initiated by another contract[22]. This can cause an oversight where ERC-20 may not properly account for the amount of ETH they have received[60]. For example, A contract might use ETH balance to calculate exchange rate dynamically. Forcing ETH by attacker may affect calculations and get lower exchange rate. To fortify this vulnerability, contract logic should avoid using exact values of the contract balance and keep track of the known deposited ETH by a new state variable. Although we use `address(this).balance` in TokenHook,

we do not check the exact value of it (*i.e.,* `address(this).balance == 0.5 ether`)—we only check whether the contract has enough ETH to send out or not. Therefore, there is no need to use a new state variable and consume more Gas to track contract's ETH. However, for developers who need to track it manually, we provide `contractBalance` variable. Two complementary functions are also considered to get current contract balance and check unexpected received ETH (*i.e.,* `getContractBalance()` and `unexpectedEther()`).

5.1.10 Unprotected SELFDESTRUCT Another vulnerability stemming from the second Parity wallet attack[3] is protecting the `SELFDESTRUCT` opcode which removes a contract from Ethereum. The self-destruct method is used to kill the contract and its associated storage. ERC-20 tokens should not contain `SELFDESTRUCT` opcode unless there is a multi approval mechanism.

5.2 A sample of best practices

In addition to reviewing known vulnerabilities, we also took into account a number of best practices for developing ERC-20 tokens. Again, due to space, we highlight a few that have been accepted by the Ethereum community to proactively prevent known vulnerabilities[12]. Some best practices are specific to ERC-20, while others are generic for all DApps—in which case, we discuss their relevance to ERC-20 and to TokenHook.

5.2.1 Compliance with ERC-20. According to the ERC-20 specifications, all six methods and two events must be implemented and are not optional. Moreover, ignoring them can cause failed function calls by other applications (*i.e.,* crypto-wallets, crypto-exchanges, web services, *etc.*) which are expecting them. Tokens that do not implement all methods (*e.g.,* `approve()` or `transferFrom()`) might also be vulnerable to complex attacks (*e.g.,* Fake deposit vulnerability[32], Missing return value bug[9]).

5.2.2 External visibility. Solidity supports two types of *function calls*: internal and external[20]. Functions calls are different than functions visibility (*i.e.,* Public, Private, Internal and External). Internal function calls expect arguments to be in memory and the EVM copies the arguments to memory. Internal calls use `JUMP` opcodes instead of creating an *EVM call*.[5] Conversely, External function calls create an *EVM call* and can read arguments directly from the `calldata` space. This is cheaper than allocating new memory and designed as a read-only byte-addressable space where the data parameter of a transaction or call is held[59]. A best practice is to use external visibility when we expect that functions will be called externally.

---

[5] Also known as "message call" when a contract calls a function of another contract.

5.2.3   Fail-Safe Mode. In the case of a detected anomaly or attack on a deployed ERC-20 token, the functionality of the token can be frozen pending further investigation. Similar to Liberty Reserve digital currency service[69], governments may compel to stop the token's ability to operate. To freeze all functionality of a token, the owner can call `pause()` function. It then sets a lock variable and methods are marked with `notPaused` modifier, throw exceptions until functionality is restored using `unpause()`.

5.2.4   Firing events. In ERC-20 standard, there are two defined events: `Approval` and `Transfer`. The first event logs successful allowance changes by token holders and the second logs successful token transfers by the `transfer()` and `transferFrom()` methods. These two events must be fired to notify external application on occurred changes. The external application (*e.g.,* TokenScope[5]) might use them to detect inconsistent behaviors, update balances, show UI notifications, or to check new token approvals. It is a best practice to fire an event for every state variable change.

5.2.5   Unexpected revert. A function that attempts to complete many operations that individually may revert could deadlock if one operation always fails. For example, `transfer()` can throw an exception—if one transfer in a sequence fails, the whole sequence fails. One standard practice is to account for ETH owed and require withdrawals through a dedicated function. In TokenHook, ETH is only transferred to a single party in a single function `sell()`. It seems overkill to implement a whole accounting system for this. As a consequence, a seller that is incapable of receiving ETH (*e.g.,* operating from a contract that is not payable) will be unable to sell their tokens for ETH. However they can recover by transferring the tokens to a new address to sell from.

5.2.6   Global or Miner controlled variables. Since malicious miners have the ability to manipulate global Solidity variables (*e.g.,* `block.timestamp`, `block.number`, `block.difficulty`, *etc.*), it is recommended to avoid these variables in ERC-20 tokens.

5.2.7   Proxy contracts. An ERC-20 token can be deployed with a pair of contracts: a proxy contract that passes through all the function calls to a second functioning ERC-20 contract[61,39]. One use of proxy contract is when upgrades are required—a new functional contract can be deployed and the proxy is modified to point at the update. Form audit point of view, it is recommended to have non-upgradable ERC-20 tokens. Initial token audit might show it as secure while the upgraded versions contains new vulnerabilities that did not exist at the time of initial audit.
